

# Structured Synchronous Reactive Programming for Game Development

## Case Study: On Rewriting Pingus from C++ to CÉU

Figure 1: Pingus gameplay.

### ABSTRACT

TODO.

**Keywords:** TODO, TODO, TODO.

### 1 INTRODUCTION

Pingus is an open-source puzzle-platform video game based on Lemmings. The objective of the game is to guide a group of penguins through a number of obstacles towards a designated exit (Figure 1). Pingus is developed in standard object-oriented C++, the *lingua franca* of game development [9]. The codebase<sup>1</sup> is about 40,000 lines of code (LoCs), divided into the engine, level editor, auxiliary libraries, and the game logic itself.

According to Tim Sweeney (of Unreal Engine fame), about half the complexity in game development resides in *simulation* (aka *game logic*), but which accounts for only 10% of the CPU budget [18]. The high development costs contrasting with the low impact on performance appeals for alternatives with productivity in mind, especially considering that it is the game logic that varies the most between projects. Sweeney states that “will gladly sacrifice 10% of our performance for 10% higher productivity”.

Object-oriented games rely on the *observer pattern* [9] to handle events from the environment (e.g., key presses and timers) and also as a notification mechanism between entities in the game logic. The observers are short-lived callbacks that have to execute as fast as possible to keep the game reactive to incoming events in real time. For this reason, callbacks cannot contain long-lasting locals and loops, which are elementary capabilities of classical structured

programming [7, 14, 1]. In this sense, callbacks actually disrupt structured programming, becoming “our generation’s *goto*”,<sup>2</sup>

CÉU [16, 15] is a programming language that offers a concurrent and expressive alternative to C/C++ with the characteristics that follow:

- *Reactive*: code only executes in reactions to events.
- *Structured*: programs use structured control mechanisms, such as `await` (to suspend a line of execution), and `par` (to combine multiple lines of execution).
- *Synchronous*: reactions run atomically and to completion on each line of execution, i.e., there’s no implicit preemption or real parallelism.

Structured reactive programming eliminates callbacks, letting programmers write code in direct and sequential style and recover from the inversion of control imposed by the observer pattern [7]. CÉU supports logical parallelism with a resource-efficient implementation in terms of memory and CPU usage [16]. The runtime is single threaded and does not rely on garbage collection.

In this work, we advocate structured synchronous reactive programming as an expressive and productive alternative for game logic development. We present a case study of rewriting Pingus from C++ to CÉU with the contributions as follows:

- Applying idiomatic code in CÉU as alternative solutions for six selected behaviors in the game logic.
- Presenting an in-depth qualitative analysis of the proposed solutions in comparison to the original implementations in C++.
- Identifying five recurrent control-flow patterns that likely apply to other games: *Finite State Machines*, *Continuation Passing*, *Dispatching Hierarchies*, *Lifespan Hierarchies*, *Signaling Mechanisms*.

A control-flow pattern is a recurring technique to describe dependencies and explicit orders between statements (or groups of statements) in a program. For instance, consider how a key press stimulus propagates through the game entities and also what happens with them if the stimulus causes the end of the game. CÉU supports primitives that help describing complex control-flow relationships in the game logic more concisely. The rewriting process consisted of identifying sets of callbacks implementing control flow in the game and translating them to CÉU using appropriate structured constructs. As an example, a double mouse click is characterized by a first click, followed by a maximum amount of time, followed by a second click. This behavior depends on different events (clicks and timers) which have to occur in a particular order. In C++, the implementation involves callbacks crossing reactions to successive events which manipulate state variables explicitly. Although we documented in detail two use cases for each of the five patterns,

<sup>1</sup>Pingus repository: [github.com/Pingus/pingus/](https://github.com/Pingus/pingus/)

<sup>2</sup>“Callbacks as our Generations’ Go To Statement”: [tirania.org/blog/archive/2013/Aug-15.html](http://tirania.org/blog/archive/2013/Aug-15.html)

in this work we only present six cases due to space constraints. This work focuses on a qualitative analysis for the programming techniques that we applied during the rewriting process. Not all techniques result in reduction in LoCs (especially considering the verbose syntax of CÉU), but have other effects such as eliminating shared variables and dependencies between classes.

The rest of the paper is organized as follows: Section 2 gives an overview of the Pingus codebases in C++ and CÉU and describes our approach to identify and rewrite the control flow in the game. Section 3 discusses six case studies in detail which are categorized in five control-flow patterns. Section 4 discusses related work. Section 5 concludes the paper.

## 2 THE PINGUS CODEBASE

In Pingus, the game logic also accounts for almost half the size of the codebase: 18.173 from 39.362 LoCs (46%) spread across 272 files. However, about half of the game logic relates to non-reactive code, such as configurations and options, saved games and serialization, maps and levels descriptions, string formatting, collision detection, graph algorithms, etc. This part remains unchanged and relies on the seamless integration between CÉU and C/C++ [16]. Therefore, we rewrote 9.186 LoCs spread across 126 files<sup>3</sup>. In order to only consider effective code in the analysis, we then removed all headers, declarations, trivial getters & setters, and other innocuous statements, resulting 4.135 dense LoCs spread across 70 implementation files originally written in C++<sup>4</sup>. We did the same with the implementation in CÉU, resulting in 3.697 dense LoCs<sup>5</sup>. Figure 2 summarizes the effective codebase in the two implementations.

Although the sections that follow compare the codebases a qualitatively, the lines with lower ratio numbers above correlate to the parts of the game logic that we consider more susceptible to structured reactive programming. For instance, the *Pingu* behavior (*ratio* 0.80) contains complex animations that are affected by timers, game rules, and user interaction. In contrast, the *Option screen* (*ratio* 0.97) is a simple UI grid with trivial mouse interactions.

As a general rewriting rule, we could identify control-flow behaviors in C++ by looking for class members with identifiers resembling verbs, statuses, and counters (e.g., `pressed`, `particle.thrown`, `mode`, and `delay.count`). Good chances are that variables with these “suspicious names” encode some form of control-flow progression that cross multiple callback invocations.

During the course of the rewriting process, we could identify more general control-flow patterns which likely apply to other games as well.

## 3 CONTROL-FLOW PATTERNS & CASE STUDIES

In this section, we select six representative game behaviors and describe in detail their implementations in C++ and CÉU. We also categorize these behaviors in five abstract control-flow patterns as follows:

1. *Finite State Machines*: Event occurrences map to transitions between states that trigger appropriate actions comprising the behavior of a game entity.
2. *Continuation Passing*: The completion of a long-lasting activity may carry a continuation, i.e., some action to execute next in the game.
3. *Dispatching Hierarchies*: Entities form a dispatching hierarchy in which a container that receives a stimulus automatically forwards it to its managed children.

4. *Lifespan Hierarchies*: Entities form a lifespan hierarchy in which a terminating container entity automatically destroys its managed children.
5. *Signaling Mechanisms*: Entities often need to communicate and affect each other explicitly through signaling mechanisms, especially if there is no hierarchy relationship between them.

### 3.1 Finite State Machines

TODO: falar do state pattern, citar game.patterns, falar que usa estado explicito

**Case Study: Detecting double-clicks in the *Armageddon button***

In Pingus, a double click in the *Armageddon button* at the bottom right of the screen literally explodes all pingus.<sup>6</sup>

Figure 3.a shows the C++ implementation for the class `ArmageddonButton` with methods for rendering the button and handling mouse and timer events. The code focus on the double click detection and hides unrelated parts with `<...>`. The methods `update` (ln. 14–26) and `on_click` (ln. 28–34) are examples of *short-lived callbacks*, which are pieces of code that execute atomically in reaction to external input events. The callback `on_click` reacts to mouse clicks detected by the base class `RectComponent` (ln. 2), while the callback `update` continuously reacts to the passage of time, frame by frame. Callbacks are short lived because they must react to input as fast as possible to let other callbacks execute, keeping the game with real-time responsiveness. The class first initializes the variable `pressed` to track the first click (ln. 3,32). It also initializes the variable `press_time` to count the time since the first click (ln. 4, 17). If another click occurs within 1 second, the class signals the double click to the application (ln. 30). Otherwise, the `pressed` and `press_time` state variables are reset (ln. 19–20). Figure 4 illustrates how we can model the double-click behavior in C++ as a state machine. The circles represent the state of the variables in the class, while the arrows represent the callbacks manipulating state. Note in the code how the accesses to the state variables are spread across the entire class. For instance, the distance between the initialization of `pressed` (ln. 3) and the last access to it (ln. 32) is over 40 lines in the original file. Arguably, this dispersion of code across methods makes the understanding and maintenance of the double-click behavior more difficult. Also, even though the state variables are private, unrelated methods such as `draw`, which is defined in middle of the class (ln. 10–12), can potentially access them.

CÉU provides structured constructs to deal with events, aiming to eradicate explicit manipulation of state variables for control-flow purposes. In Figure 3.b, the loop detection (ln. 4–10) awaits the first click (ln. 5) and then, while watching 1 second (ln. 6–9), awaits the second click (ln. 7). If the second click occurs within 1 second, the `break` terminates the loop (ln. 8) and the `emit` signals the double click to the application (ln. 12). Otherwise, the `watching` block as a whole aborts after 1 second and the loop restarts, falling back to the first click `await` (ln. 5). Double click detection in CÉU doesn’t require state variables and is entirely self-contained in the `loop` body (ln. 4–10). Also, these 7 lines of code *only* detect the double click, leaving the actual effect to happen outside the loop (ln. 12).

Figure 2: The Pingu codebase directory tree.

The *Bomber action* explodes the clicked pingu, throwing particles around and also destroying the terrain under its radius.<sup>7</sup> We can model the explosion animation with a sequential state machine (Figure 5) with actions associated to specific frames as follows<sup>8</sup>:

1. 0th frame: plays a "Oh no!" sound.
2. 10th frame: plays a "Bomb!" sound.
3. 13th frame: throws particles, destroys the terrain, and shows an explosion sprite.
4. Game tick: hides the explosion sprite.
5. Last frame: kills the pingu.

Figure 6 compares the implementations in C++ and C  U.

In C++, the class `Bomber` defines the callbacks `draw` and `update` to manage the state machine described above. The class first defines one state variable for each action to perform (ln. 4–7). The "Oh no!" sound plays as soon as the object starts in *state-1* (ln. 11). The `update` callback (ln. 14–38) first updates the pingu animation and movement on every frame regardless of its current state (ln. 15–16). When the animation reaches the 10th frame, it plays the "Bomb!" sound and switches to *state-2* (ln. 18–22). The state variable `soundPlayed` is required because the sprite frame doesn't necessarily advance on every `update` invocation (e.g., `update` may execute twice during the 10th frame). The same reasoning and technique applies to *state-3* (ln. 24–32 and 43–44). The explosion sprite appears in a single frame in *state-4* (ln. 45). Finally, the pingu dies after the animation frames terminate (ln. 34–35). Note that a single numeric state variable suffices to track the states, but the original authors probably chose to encode each state in an independent boolean variable to rearrange and experiment with them during development. Still, due to the short-lived nature of callbacks, state variables are unavoidable and are actually the essence of object-oriented programming (i.e., *methods + mutable state*). Like double click detection in C++, note that the state machine is encoded across 3 different methods, each intermixing code with unrelated functionality.

The equivalent code for the *Bomber action* in C  U doesn't require state variables and reflects the sequential state machine implicitly, using `await` statements in direct style to separate the actions. The `Bomber` is a `code/await` abstraction of C  U, which is

<sup>7</sup>Bomber action animation: [github.com/an000/p/blob/master/README.md#2](https://github.com/an000/p/blob/master/README.md#2)

<sup>8</sup>State machine animation: [github.com/an000/p/blob/master/README.md#3](https://github.com/an000/p/blob/master/README.md#3)

similar to a coroutine or fiber [1]: a subroutine that retains runtime state, such as local variables and the program counter, across reactions to events (i.e., across `await` statements). The pingu movement and sprite animation are isolated in two other `code/await` abstractions and execute in separate through the `spawn` primitive (ln. 4–5). The event `game.dt` (ln. 12,16,24) is analogous to the `update` callback of C++ and occurs on every frame. The code tracks the animation aliveness (ln. 7–27) and, on termination, performs the last bomber action (ln. 30). As soon as the animation starts, the code performs the first action (ln. 9). The intermediate actions are performed when the corresponding conditions occur (ln. 12,16,24). The `do-end` block (ln. 19–25), restricts the lifespan of the single-frame explosion sprite (ln. 21): after the next game tick (ln. 24), the block terminates and automatically destroys the spawned abstraction (removing it from the screen). In contrast with the implementation in C++, all actions happen in a contiguous chunk of code (ln. 5–30) which handles no extra functionality.

## 3.2 Continuation Passing

TODO: what is this?

### Case Study: Advancing Pages in the Story screen

The clickable *blue dots* in the campaign world map transit to ambience story screens<sup>9</sup>. A story is composed of multiple pages and, inside each page, the words of the story appear incrementally over time. A first click in the button `>>>` fast forwards the words to show the full page. A second click advances to the next page, until the story terminates. If the page completes before a click (due to the time elapsing), a first click advances to the next page. Figure 8 compares the implementations in C++ and C  U.

In C++, the class `StoryScreenComponent` implements the method `next_text`, which is a callback for clicks in `>>>`. The variable `'pages'` (ln. 4–5, 24–26) is a vector holding each page, but which also encodes *continuations* for the story progress: each call to `next_text` that advances the story (ln. 23–32) removes the current page (ln. 24) and sets the next action to perform (i.e., "display a new page") in the variable `current_page` (ln. 26). Figure 7 illustrates the continuation mechanism to advance pages and also a state machine for fast forwarding words (inside the dashed rectangle). The state variable `displayed` (ln. 6,15,20,21,27) switches between the behaviors "advancing text" and "advancing pages", which are both handled intermixed inside the method `next_text`.

The code in C  U uses the internal event `next_text`, which is emitted from clicks in `>>>`. The sequential navigation from page to page uses a loop in direct style (ln. 6–15) instead of explicit state

variables for the continuation and state machine. While the text advances in an inner loop (hidden in ln. 9), we watch the `next_text` event that fast forwards it. The loop may also eventually terminate with the time elapsing normally. This way, we do not need a variable (such as ‘displayed’ in C++) to switch between the states “advancing text” and “advancing pages”. The `par/or` makes the page advance logic to execute in parallel with the redrawing code (ln. 13). Whenever the page advances, the redrawing code is automatically aborted (due to the `or` modifier). The `await next_text` in sequence (ln. 11) is the condition to advance to the next page. Note that, unlike the implementation in C++, the “advancing text” behavior is not intermixed with the “advancing pages” behavior, instead, it is encapsulated inside the inner loop nested with a deeper indentation (ln. 9).

### 3.3 Dispatching Hierarchies

#### Case Study: *Bomber* action `draw` and `update` dispatching

Figure 5: State machine for the *Bomber* animation sequence.

#### TODO

Figure 10 compares the implementations in C++ and CéU.

In C++, the class `Bomber` declares a `sprite` member to handle its animation frames (Figure 5). The `Sprite` class is part of the game engine and knows how to update and render itself. However, the `Bomber` still has to respond to `update` and `draw` requests from the game and forward them to the `sprite` (ln. 11–13 and 15–18). To understand how the `update` callback flows from the original environment stimulus from the game down to the `sprite`, we need to follow a long chain of 7 method dispatches (Figure 9):

1. `ScreenManager::display` in the main game loop calls `update`.
2. `ScreenManager::update` calls `last_screen->update` for the active game screen (a `GameSession` instance, considering the

```

[b] Implementation in CéU

Figure 6: The *Bomber* action sequence.

Bomber).

3. `GameSession::update` calls `world->update`.
4. `World::update` calls `obj->update` for each object in the world.
5. `PinguHolder::update` calls `pingu->update` for each pingu alive.
6. `Pingu::update` calls `action->update` for the active pingu action.
7. `Bomber::update` calls `sprite.update`. `Sprite::update` finally updates the animation frame.

Each dispatching step in the chain is necessary considering the game architecture:

- With a single assignment to `last_screen`, we can easily deactivate the current screen and redirect all dispatches to a new screen.
- The `World` class manages and dispatches events to all game entities, such as all pingus and traps, with the common interface `WorldObj`.
- Since it is common to iterate only over the pingus (vs. all world objects), the container `PinguHolder` manages all pingus.
- Since a single pingu can change between actions during lifetime, the `action` member decouples them with another level

Figure 7: State machine for advancing pages in the *Story* screen.

of indirection.

- Sprites are part of the game engine and are reusable everywhere (e.g., UI buttons, world objects, etc.), so it is also convenient to decouple them from actions.

The `draw` callback flows through the same dispatching hierarchy until reaching the `Sprite` class.

In CÉU, the `Bomber` action spawns a `Sprite` animation instance on its body. The `Sprite` instance (ln. 3) can react directly to external `dt` and `redraw` events (which are analogous to `update` and `redraw` callbacks, respectively), bypassing the program hierarchy entirely. While and *only while* the bomber abstraction is alive, the sprite animation is also alive. The radical decoupling between the program hierarchy and reactions to events eliminates dispatching chains entirely.

### 3.4 Lifespan Hierarchies

#### Case Study: Managing the Pingu Lifecycle

A pingu is a dynamic entity created periodically and destroyed under certain conditions, such as falling from a high altitude<sup>10</sup>. Figure 11 compares the implementations in C++ and CÉU.

In C++, the class `PinguHolder` is a container that holds all pinguos alive. The method `PinguHolder::create_pingu` (ln. 1–6) is called periodically to create a new `Pingu` and add it to the `pingus` collection (ln. 3–4). The method `PinguHolder::update` (ln. 8–18) checks the state of all pinguos on every frame, removing those with the dead status (ln. 12–14). Entities with dynamic lifespan in C++ require explicit `add` and `remove` calls associated to a container (ln. 4,13). Without the `erase` call above, a dead pingu would remain in the collection with updates on every frame (ln. 11). Since the `redraw` behavior for a dead pingu is innocuous, the death could go unnoticed but the program would keep consuming memory and CPU time. This problem is known as the *lapsed listener* [9] and also occurs in languages with garbage collection: A container typically holds a strong reference to a child (sometimes the only reference to it), and the runtime cannot magically detect it as garbage.

CÉU supports `pool` declarations to hold dynamic abstraction instances. Additionally, the `spawn` statement supports a pool identifier to associate the new instance with a pool. The game screen spawns a new `Pingu` on every invocation of `Pingu.Spawn`. The `spawn` statement (ln. 6) specifies the pool declared at the top-level block of the game screen (ln. 3). In this case, the lifespan of the new instances follows the scope of the pool (ln. 1–9) instead of the enclosing scope of the `spawn` statement (ln. 4–7). Since pools are also subject to lexical scope, the lifespan of all dynamically allocated pinguos is constrained to the game screen. Lexical scopes handle memory and event dispatching automatically for static instances and also for pools. However, the lifespan of a dynamic instance does not necessarily have to match the lifespan of its associated pool (Figure 12).

<sup>10</sup>Death of pinguos animation: [github.com/an000/p/blob/master/README.md#5](https://github.com/an000/p/blob/master/README.md#5)

In CÉU, when the execution block of a dynamic instance terminates, which characterizes its *natural termination*, the instance is automatically removed from its pool. Therefore, dynamic instances do not require any extra bookkeeping related to containers or explicit deallocation. To remove a pingu from the game in CÉU, we just need to terminate its execution block according to the appropriate conditions: The `escape` statement (ln. 17) aborts the execution block of the `Pingu` instance, removing it from its associated pool automatically. Hence, a dynamic instance that terminates naturally leaves no traces in the program.

### 3.5 Signaling Mechanisms

#### Case Study: Global Keys and the Options Menu

The *mouse grab option* restricts the mouse movement to the game window boundaries<sup>11</sup>. The option can be set anywhere in the game by pressing `Ctrl-G`. In addition, the *Options menu* has a check box to toggle the *mouse grab option* with mouse clicks while still responding to `Ctrl-G` presses. Figure 14 compares the implementations in C++ and CÉU.

The implementations in C++ and CÉU use a signalling mechanism to connect the key presses, the check box, and a configuration manager that applies the appropriate side effects in the game (i.e., restrict the mouse movement). Figure 13 illustrates how the mutual notifications create a dependency cycle between the configuration manager and the check box.

In C++, the class `GlbEvt` detects `Ctrl-G` presses and invokes the callback `config_manager.set_grab` (ln. 5–8). The class `CfgMgr` uses a `boost::signal` (ln. 16) to notify the application when the new configuration is applied (ln. 22). The `if` enclosing the signal emission (ln. 20–23) breaks the dependency cycle of Figure 13 and prevents an infinite execution loop. The class `ChkBox` also uses a `boost::signal` (ln. 28) to notify the application on changes (ln. 33). Again, the `if` enclosing the signal emission (ln. 32–34) breaks the dependency cycle of Figure 13 to avoid infinite execution. The class `OptMenu` creates the dependency loop by connecting the two signals. The constructor binds the signal `config_manager.on_grab_change` to the callback method `grab_box->set` (ln. 48–52), and also the signal `grab_box->on_change` to the callback method `config_manager.set_grab` (ln. 53–57). This way, every time the `CfgMgr` signals `on_grab_change` (ln. 22), the method `set` is implicitly called. The same happens between the signal `on_change` in the `ChkBox` and the method `set_grab` in the `CfgMgr` (ln. 18). Note that the signal binding to call `ChkBox::set` (ln. 50) receives a fixed value `false` as the last argument to prevent infinite execution (ln. 30). The `OptMenu` destructor (ln. 62–66) breaks the connections explicitly when the *Option screen* terminates.

In CÉU, a `Ctrl-G` key press broadcasts the internal event `config_manager.go_grab` to the application (ln. 8). The configuration manager just needs to react to `go_grab` continuously to perform the *grab* effect (ln. 25–27). The `ChkBox` exposes the event `go_click` for notifications in both directions, i.e., from the abstraction to the application and *vice versa*: The abstraction reacts to external clicks continuously (ln. 41–43) to broadcast the event `go_click` (ln. 47). It also reacts continuously to `go_click` in another line of execution (ln. 45–48), which awakes from notifications from the first line of execution or from the application. The `OptMenu` connects the two events as follows: The two loops in parallel handle the connections in opposite directions: from the configuration manager to the check box (ln. 60–62); and from the check box to the configuration manager (ln. 65–67). When the *Option screen* terminates, the connections break automatically since the body with the two loops is automatically aborted. Note that the implementation in CÉU does not check event emits to break the dependency cycle and prevent

infinite execution. Due to the stack-based execution for internal events in CéU [16], programs with mutually-dependent events do not create infinite execution loops.

#### 4 RELATED WORK

The control-flow patterns closely relate to the *GoF* behavioral patterns [5], which some previous work discuss in the context of video game development [9, 13, 2]. The original game in C++ uses variations of the *state* (Sections 3.1 and 3.2), *visitor* (Sections 3.3 and 3.4), and *observer* (Section 3.5 and to handle input in general) patterns as implementation details to achieve the desired higher-level control-flow patterns. CéU overcomes the need of be-

havioral patterns with a semantics that supports structured control-flow mechanisms and event-based communication via broadcast. As an example, the *state pattern* for the bomber animation in Section 3.1 becomes a series of blocks separated by `await` statements.

A number of domain-specific languages, frameworks, and techniques have been proposed for particular subsystems of the game logic, such as animations [10, 4, 11, 12], game state and screen progression [19, 8], and behavior and AI modeling [6, ?] CéU is a superset of C targeting reactive systems in general and has been adopted in other domains, such as wireless sensor networks [16, 3] and multimedia systems [17]. core of the game, even eliminating parts of a game engine such as ... - concurrency synchronous

Functional reactive programming is an FRP - interfacing with C - live porting

different - generally? - most examples abstracted - imagine um jogo... - assim poderíamos aplicar... - sem código real - não aplicam a jogos existentes - propõem soluções - eliminam o visitante, adotado na linguagem

- padrões - subgames - gpp - control-flow patterns that are recurrent in Pingu and likely apply to other games - also, not identifying and applying, but applying in idiomatic code in another language

- como é diferente de GoF - not much unlike behavioral patterns

Design patterns for games can be approached from two different perspectives; firstly as patterns used for describing the game mechanics (gameplay and game rules) and secondly as the use of object-oriented design patterns in programming games. Concerning game mechanics, Bjork et al. [4] introduced a set of design patterns which essentially are descriptions (employing a unified vo-

cabulary) of reoccurring interaction schemes relevant to games story and gameplay. As such, these patterns are not related to the software architecture or code. The proposed patterns are collected from interviewing professional game programmers, from analyzing existing games and from transforming game mechanics.

TODO: - FSMs - BTs - FRP

## 5 CONCLUSION

TODO: non reactive, C++ integration - TODO: OO state + methods - eliminar estados explicitos com estruturas de controle apropriadas

We promote the *structured synchronous reactive* programming model of C  U for the development of games. We present in-depth use cases categorized in 5 control-flow patterns applied to *Pingus* (an open-source *Lemmings* clone) that likely apply to other games.

We show how the standard way to program games with objects and callbacks in C++ hinders structured programming techniques, such as support for sequential execution, long-lasting loops, and persisting local variables. In this sense, callbacks actually disrupt structured programming, becoming [“our generations goto”][goto]

according to Miguel de Icaza.

Overall, we believe that most difficulties in implementing control behavior in game logic is not inherent to this domain, but a result of accidental complexity due to the lack of structured abstractions and an appropriate concurrency model to handle event-based applications.
